# Preface

These are class notes for the course STAT303-3. This is not the course text-book. You are required to read the relevant sections of the book as mentioned on the course website.

The course notes are currently being written, and will continue to being developed as the course progresses (just like the class notes last quarter). Please report any typos / mistakes / inconsistencies / issues with the class notes / class presentations in your comments [here](#). Thank you!

## **Part I**

# **Moving towards non-linearity**

# 1 Introduction to scikit-learn

In this chapter, we'll learn some functions from the library `sklearn` that will be useful in:

1. Splitting the data into `train` and `test`
2. Scaling data
3. Fitting a model
4. Computing model performance metrics
5. Tuning model hyperparameters\* to optimize the desired performance metric

*\*In machine learning, a model hyperparameter is a parameter that cannot be learned from training data and must be set before training the model. Hyperparameters control aspects of the model's behavior and can greatly impact its performance. For example, the regularization parameter  $\lambda$ , in linear regression is a hyperparameter. You need to specify it before fitting the model. On the other hand, the beta coefficients in linear regression are parameters, as you learn them while training the model, and don't need to specify their values beforehand.*

We'll use a classification problem to illustrate the functions. However, similar functions can be used for regression problems, i.e., prediction problems with a continuous response.

```
import pandas as pd
import numpy as np
import matplotlib.pyplot as plt
import seaborn as sns
sns.set(font_scale=1.35)
```

Let us import the `sklearn` modules useful in developing statistical models.

```
# sklearn has 100s of models - grouped in sublibraries, such as linear_model
from sklearn.linear_model import LogisticRegression, LinearRegression

# sklearn has many tools for cleaning/processing data, also grouped in sublibraries
# splitting one dataset into train and test, computing cross validation score, cross validation
from sklearn.model_selection import train_test_split, cross_val_predict, cross_val_score
```

```
#sklearn module for scaling data
from sklearn.preprocessing import StandardScaler

#sklearn modules for computing the performance metrics
from sklearn.metrics import accuracy_score, mean_absolute_error, mean_squared_error, r2_score, roc_curve, auc, precision_score, recall_score, confusion_matrix

#Reading data
data = pd.read_csv('./Datasets/diabetes.csv')
```

Scikit-learn doesn't support the formula-like syntax of specifying the response and the predictors as in the `statsmodels` library. We need to create separate objects for predictors and response, which should be *array-like*. A Pandas DataFrame / Series or a Numpy array are *array-like* objects.

Let us reference our predictors as object `X`, and the response as object `y`.

```
# Separating the predictors and response - THIS IS HOW ALL SKLEARN OBJECTS ACCEPT DATA (diabetes)
y = data.Outcome
X = data.drop("Outcome", axis = 1)
```

## 1.1 Splitting data into train and test

Let us create train and test datasets for developing a model to predict if a person has diabetes.

```
# Creating training and test data
# 80-20 split, which is usual - 70-30 split is also fine, 90-10 is fine if the dataset is small
# random_state to set a random seed for the splitting - reproducible results
X_train, X_test, y_train, y_test = train_test_split(X, y, test_size = 0.2, random_state = 42)
```

Let us find the proportion of classes (‘*having diabetes*’ ( $y = 1$ ) or ‘*not having diabetes*’ ( $y = 0$ )) in the complete dataset.

```
#Proportion of 0s and 1s in the complete data
y.value_counts()/y.shape
```

```
0    0.651042
1    0.348958
Name: Outcome, dtype: float64
```

Let us find the proportion of classes (*‘having diabetes’* ( $y = 1$ ) or *‘not having diabetes’* ( $y = 0$ )) in the train dataset.

```
#Proportion of 0s and 1s in train data
y_train.value_counts()/y_train.shape
```

```
0    0.644951
1    0.355049
Name: Outcome, dtype: float64
```

```
#Proportion of 0s and 1s in test data
y_test.value_counts()/y_test.shape
```

```
0    0.675325
1    0.324675
Name: Outcome, dtype: float64
```

We observe that the proportion of 0s and 1s in the `train` and `test` dataset are slightly different from that in the complete `data`. In order for these datasets to be more representative of the population, they should have a proportion of 0s and 1s similar to that in the complete dataset. This is especially critical in case of imbalanced datasets, where one class is represented by a significantly smaller number of instances than the other(s).

When training a classification model on an imbalanced dataset, the model might not learn enough about the minority class, which can lead to poor generalization performance on new data. This happens because the model is biased towards the majority class, and it might even predict all instances as belonging to the majority class.

### 1.1.1 Stratified splitting

We will use the argument `stratify` to obtain a proportion of 0s and 1s in the `train` and `test` datasets that is similar to the proportion in the complete `data`.

```
#Stratified train-test split
X_train_stratified, X_test_stratified, y_train_stratified,\
y_test_stratified = train_test_split(X, y, test_size = 0.2, random_state = 45, stratify=y)

#Proportion of 0s and 1s in train data with stratified split
y_train_stratified.value_counts()/y_train.shape
```

```
0    0.651466
1    0.348534
Name: Outcome, dtype: float64
```

```
#Proportion of 0s and 1s in test data with stratified split
y_test_stratified.value_counts()/y_test.shape
```

```
0    0.649351
1    0.350649
Name: Outcome, dtype: float64
```

The proportion of the classes in the stratified split mimics the proportion in the complete dataset more closely.

By using stratified splitting, we ensure that both the `train` and `test` data sets have the same proportion of instances from each class, which means that the model will see enough instances from the minority class during training. This, in turn, helps the model learn to distinguish between the classes better, leading to better performance on new data.

Thus, stratified splitting helps to ensure that the model sees enough instances from each class during training, which can improve the model's ability to generalize to new data, particularly in cases where one class is underrepresented in the dataset.

Let us develop a logistic regression model for predicting if a person has diabetes.

## 1.2 Scaling data

In certain models, it may be important to scale data for various reasons. In a logistic regression model, scaling can help with model convergence. Scikit-learn uses a method known as gradient-descent (*not in scope of the syllabus of this course*) to obtain a solution. In case the predictors have different orders of magnitude, the algorithm may fail to converge. In such cases, it is useful to standardize the predictors so that all of them are at the same scale.

```
# With linear/logistic regression in scikit-learn, especially when the predictors have dif
# of magn., scaling is necessary. This is to enable the training algo. which we did not co
scaler = StandardScaler().fit(X_train)
X_train_scaled = scaler.transform(X_train)
X_test_scaled = scaler.transform(X_test) # Do NOT refit the scaler with the test data, jus
```

## 1.3 Fitting a model

Let us fit a logistic regression model for predicting if a person has diabetes. Let us try fitting a model with the un-scaled data.

```
# Create a model object - not trained yet
logreg = LogisticRegression()

# Train the model
logreg.fit(X_train, y_train)
```

```
C:\Users\akl0407\Anaconda3\lib\site-packages\sklearn\linear_model\_logistic.py:763: ConvergenceWarning:
STOP: TOTAL NO. of ITERATIONS REACHED LIMIT.
```

Increase the number of iterations (`max_iter`) or scale the data as shown in:

<https://scikit-learn.org/stable/modules/preprocessing.html>

Please also refer to the documentation for alternative solver options:

[https://scikit-learn.org/stable/modules/linear\\_model.html#logistic-regression](https://scikit-learn.org/stable/modules/linear_model.html#logistic-regression)

```
n_iter_i = _check_optimize_result(
```

```
LogisticRegression()
```

Note that the model with the un-scaled predictors fails to converge. Check out the data `X_train` to see that this may be probably due to the predictors have different orders of magnitude. For example, the predictor `DiabetesPedigreeFunction` has values in `[0.078, 2.42]`, while the predictor `Insulin` has values in `[0, 800]`.

Let us fit the model to the scaled data.

```
# Create a model - not trained yet
logreg = LogisticRegression()

# Train the model
logreg.fit(X_train_scaled, y_train)
```

```
LogisticRegression()
```

The model converges to a solution with the scaled data!

The coefficients of the model can be returned with the `coef_` attribute of the `LogisticRegression()` object. However, the output is not as well formatted as in the case of the `statsmodels` library since `sklearn` is developed primarily for the purpose of prediction, and not inference.

```
# Use coef_ to return the coefficients - only log reg inference you can do with sklearn
print(logreg.coef_)
```

```
[[ 0.32572891  1.20110566 -0.32046591  0.06849882 -0.21727131  0.72619528
  0.40088897  0.29698818]]
```

## 1.4 Computing performance metrics

### 1.4.1 Accuracy

Let us test the model prediction accuracy on the test data. We'll demonstrate two different functions that can be used to compute model accuracy - `accuracy_score()`, and `score()`.

The `accuracy_score()` function from the `metrics` module of the `sklearn` library is general, and can be used for any classification model. We'll use it along with the `predict()` method of the `LogisticRegression()` object, which returns the predicted class based on a threshold probability of 0.5.

```
# Get the predicted classes first
y_pred = logreg.predict(X_test_scaled)

# Use the predicted and true classes for accuracy
print(accuracy_score(y_pred, y_test)*100)
```

```
73.37662337662337
```

The `score()` method of the `LogisticRegression()` object can be used to compute the accuracy only for a logistic regression model. Note that for a `LinearRegression()` object, the `score()` method will return the model *R*-squared.

```
# Use .score with test predictors and response to get the accuracy
# Implements the same thing under the hood
print(logreg.score(X_test_scaled, y_test)*100)
```

```
73.37662337662337
```

### 1.4.2 ROC-AUC

The `roc_curve()` and `auc()` functions from the `metrics` module of the `sklearn` library can be used to compute the ROC-AUC, or the area under the ROC curve. Note that for computing ROC-AUC, we need the predicted probability, instead of the predicted class. Thus, we'll use the `predict_proba()` method of the `LogisticRegression()` object, which returns the predicted probability for the observation to belong to each of the classes, instead of using the `predict()` method, which returns the predicted class based on threshold probability of 0.5.

```
#Computing the predicted probability for the observation to belong to the positive class (
#The 2nd column in the output of predict_proba() consists of the probability of the observ
#belong to the positive class (y=1)
y_pred_prob = logreg.predict_proba(X_test_scaled)[:,-1]

#Using the predicted probability computed above to find ROC-AUC
fpr, tpr, auc_thresholds = roc_curve(y_test, y_pred_prob)
print(auc(fpr, tpr))# AUC of ROC
```

0.7923076923076922

### 1.4.3 Confusion matrix & precision-recall

The `confusion_matrix()`, `precision_score()`, and `recall_score()` functions from the `metrics` module of the `sklearn` library can be used to compute the confusion matrix, precision, and recall respectively.

```
#Confusion matrix
cm = pd.DataFrame(confusion_matrix(y_test, y_pred), columns=['Predicted 0', 'Predicted 1'],
                  index = ['Actual 0', 'Actual 1'])
sns.heatmap(cm, annot=True, cmap='Blues', fmt='g');
```

```
print("Precision: ", precision_score(y_test, y_pred))  
print("Recall: ", recall_score(y_test, y_pred))
```

Precision: 0.6046511627906976  
Recall: 0.52

Let us compute the performance metrics if we develop the model using stratified splitting.

```
# Developing the model with stratified splitting  
  
#Scaling data  
scaler = StandardScaler().fit(X_train_stratified)  
X_train_stratified_scaled = scaler.transform(X_train_stratified)  
X_test_stratified_scaled = scaler.transform(X_test_stratified)  
  
# Training the model  
logreg.fit(X_train_stratified_scaled, y_train_stratified)
```

```

#Computing the accuracy
y_pred_stratified = logreg.predict(X_test_stratified_scaled)
print("Accuracy: ",accuracy_score(y_pred_stratified, y_test_stratified)*100)

#Computing the ROC-AUC
y_pred_stratified_prob = logreg.predict_proba(X_test_stratified_scaled)[: ,1]
fpr, tpr, auc_thresholds = roc_curve(y_test_stratified, y_pred_stratified_prob)
print("ROC-AUC: ",auc(fpr, tpr))# AUC of ROC

#Computing the precision and recall
print("Precision: ", precision_score(y_test_stratified, y_pred_stratified))
print("Recall: ", recall_score(y_test_stratified, y_pred_stratified))

#Confusion matrix
cm = pd.DataFrame(confusion_matrix(y_test_stratified, y_pred_stratified), columns=['Predicted 0', 'Predicted 1'],
                  index = ['Actual 0', 'Actual 1'])
sns.heatmap(cm, annot=True, cmap='Blues', fmt='g');

```

```

Accuracy: 78.57142857142857
ROC-AUC: 0.8505555555555556
Precision: 0.7692307692307693
Recall: 0.5555555555555556

```

The model with the stratified train-test split has a better performance as compared to the other model on all the performance metrics!

## 1.5 Tuning the model hyperparameters

A hyperparameter (among others) that can be trained in a logistic regression model is the regularization parameter.

We may also wish to tune the decision threshold probability. Note that the decision threshold probability is not considered a hyperparameter of the model. Hyperparameters are model parameters that are set prior to training and cannot be directly adjusted by the model during training. Examples of hyperparameters in a logistic regression model include the regularization parameter, and the type of shrinkage penalty - lasso / ridge. These hyperparameters are typically optimized through a separate tuning process, such as cross-validation or grid search, before training the final model.

The performance metrics can be computed using a desired value of the threshold probability. Let us compute the performance metrics for a desired threshold probability of 0.3.

```

# Performance metrics computation for a desired threshold probability of 0.3
desired_threshold = 0.3

# Classifying observations in the positive class (y = 1) if the predicted probability is g
# than the desired decision threshold probability
y_pred_desired_threshold = y_pred_stratified_prob > desired_threshold
y_pred_desired_threshold = y_pred_desired_threshold.astype(int)

#Computing the accuracy
print("Accuracy: ",accuracy_score(y_pred_desired_threshold, y_test_stratified)*100)

#Computing the ROC-AUC
fpr, tpr, auc_thresholds = roc_curve(y_test_stratified, y_pred_stratified_prob)
print("ROC-AUC: ",auc(fpr, tpr))# AUC of ROC

#Computing the precision and recall
print("Precision: ", precision_score(y_test_stratified, y_pred_desired_threshold))
print("Recall: ", recall_score(y_test_stratified, y_pred_desired_threshold))

#Confusion matrix
cm = pd.DataFrame(confusion_matrix(y_test_stratified, y_pred_desired_threshold),
                  columns=['Predicted 0', 'Predicted 1'], index = ['Actual 0', 'Actual 1'])
sns.heatmap(cm, annot=True, cmap='Blues', fmt='g');

```

```

Accuracy: 75.32467532467533
ROC-AUC: 0.8505555555555556
Precision: 0.6111111111111112
Recall: 0.8148148148148148

```

### 1.5.1 Tuning decision threshold probability

Suppose we wish to find the optimal decision threshold probability to maximize accuracy. Note that we cannot use the test dataset to optimize model hyperparameters, as that may lead to overfitting on the test data. We'll use  $K$ -fold cross validation on train data to find the optimal decision threshold probability.

We'll use the `cross_val_predict()` function from the `model_selection` module of `sklearn` to compute the  $K$ -fold cross validated predicted probabilities. Note that this function simplifies the task of manually creating the  $K$ -folds, training the model  $K$ -times, and computing the predicted probabilities on each of the  $K$ -folds. Thereafter, the predicted probabilities will be used to find the one the optimal threshold probability that maximizes the classification accuracy.

```
hyperparam_vals = np.arange(0,1.01,0.01)
accuracy_iter = []

predicted_probability = cross_val_predict(LogisticRegression(), X_train_stratified_scaled,
```

```

y_train_stratified, cv = 5, method = 'predic

for threshold_prob in hyperparam_vals:
    predicted_class = predicted_probability[:,1] > threshold_prob
    predicted_class = predicted_class.astype(int)

    #Computing the accuracy
    accuracy = accuracy_score(predicted_class, y_train_stratified)*100
    accuracy_iter.append(accuracy)

```

Let us visualize the accuracy with change in decision threshold probability.

```

# Accuracy vs decision threshold probability
sns.scatterplot(x = hyperparam_vals, y = accuracy_iter)
plt.xlabel('Decision threshold probability')
plt.ylabel('Average 5-fold CV accuracy');

```

The optimal decision threshold probability is the one that maximizes the  $K$ -fold cross validation accuracy.

```
# Optimal decision threshold probability
hyperparam_vals[accuracy_iter.index(max(accuracy_iter))]
```

0.46

```
# Performance metrics computation for the optimum decision threshold probability
desired_threshold = 0.46

# Classifying observations in the positive class (y = 1) if the predicted probability is g
# than the desired decision threshold probability
y_pred_desired_threshold = y_pred_stratified_prob > desired_threshold
y_pred_desired_threshold = y_pred_desired_threshold.astype(int)

#Computing the accuracy
print("Accuracy: ",accuracy_score(y_pred_desired_threshold, y_test_stratified)*100)

#Computing the ROC-AUC
fpr, tpr, auc_thresholds = roc_curve(y_test_stratified, y_pred_stratified_prob)
print("ROC-AUC: ",auc(fpr, tpr))# AUC of ROC

#Computing the precision and recall
print("Precision: ", precision_score(y_test_stratified, y_pred_desired_threshold))
print("Recall: ", recall_score(y_test_stratified, y_pred_desired_threshold))

#Confusion matrix
cm = pd.DataFrame(confusion_matrix(y_test_stratified, y_pred_desired_threshold),
                  columns=['Predicted 0', 'Predicted 1'], index = ['Actual 0', 'Actual 1'])
sns.heatmap(cm, annot=True, cmap='Blues', fmt='g');
```

```
Accuracy: 79.87012987012987
ROC-AUC: 0.8505555555555556
Precision: 0.7804878048780488
Recall: 0.5925925925925926
```

Model performance on test data has improved with the optimal decision threshold probability.

### 1.5.2 Tuning the regularization parameter

The `LogisticRegression()` method has a default  $L2$  regularization penalty, which means ridge regression.  $C$  is  $1/\lambda$ , where  $\lambda$  is the hyperparameter that is multiplied with the ridge penalty.  $C$  is 1 by default.

```
accuracy_iter = []
hyperparam_vals = 10**np.linspace(-3.5, 1)

for c_val in hyperparam_vals: # For each possible C value in your grid
    logreg_model = LogisticRegression(C=c_val) # Create a model with the C value

    accuracy_iter.append(cross_val_score(logreg_model, X_train_stratified_scaled, y_train_
                                         scoring='accuracy', cv=5)) # Find the cv results
```

```
plt.plot(hyperparam_vals, np.mean(np.array(accuracy_iter), axis=1))
plt.xlabel('C')
plt.ylabel('Average 5-fold CV accuracy')
plt.xscale('log')
plt.show()
```

```
# Optimal value of the regularization parameter 'C'
optimal_C = hyperparam_vals[np.argmax(np.array(accuracy_iter).mean(axis=1))]
optimal_C
```

0.11787686347935879

```
# Developing the model with stratified splitting and optimal 'C'

#Scaling data
scaler = StandardScaler().fit(X_train_stratified)
X_train_stratified_scaled = scaler.transform(X_train_stratified)
```

```

X_test_stratified_scaled = scaler.transform(X_test_stratified)

# Training the model
logreg = LogisticRegression(C = optimal_C)
logreg.fit(X_train_stratified_scaled, y_train_stratified)

#Computing the accuracy
y_pred_stratified = logreg.predict(X_test_stratified_scaled)
print("Accuracy: ",accuracy_score(y_pred_stratified, y_test_stratified)*100)

#Computing the ROC-AUC
y_pred_stratified_prob = logreg.predict_proba(X_test_stratified_scaled)[:,-1]
fpr, tpr, auc_thresholds = roc_curve(y_test_stratified, y_pred_stratified_prob)
print("ROC-AUC: ",auc(fpr, tpr))# AUC of ROC

#Computing the precision and recall
print("Precision: ", precision_score(y_test_stratified, y_pred_stratified))
print("Recall: ", recall_score(y_test_stratified, y_pred_stratified))

#Confusion matrix
cm = pd.DataFrame(confusion_matrix(y_test_stratified, y_pred_stratified), columns=['Predicted 0', 'Predicted 1'],
                  index = ['Actual 0', 'Actual 1'])
sns.heatmap(cm, annot=True, cmap='Blues', fmt='g');

```

```

Accuracy: 78.57142857142857
ROC-AUC: 0.8516666666666666
Precision: 0.7837837837837838
Recall: 0.5370370370370371

```

### 1.5.3 Tuning the decision threshold probability and the regularization parameter simultaneously

```
threshold_hyperparam_vals = np.arange(0,1.01,0.01)
C_hyperparam_vals = 10**np.linspace(-3.5, 1)
accuracy_iter = []

for c_val in C_hyperparam_vals:
    predicted_probability = cross_val_predict(LogisticRegression(C = c_val), X_train_stratified,
                                              y_train_stratified, cv = 5, method = 'pr

    for threshold_prob in threshold_hyperparam_vals:
        predicted_class = predicted_probability[:,1] > threshold_prob
        predicted_class = predicted_class.astype(int)

        #Computing the accuracy
        accuracy = accuracy_score(predicted_class, y_train_stratified)*100

 Recall: 0.5925925925925926

Later in the course, we'll see the `sklearn` function `GridSearchCV`, which is used to optimize several model hyperparameters simultaneously with  $K$ -fold cross validation, while avoiding for loops.

## 2 Regression splines

*Read sections 7.1-7.4 of the book before using these notes.*

*Note that in this course, lecture notes are not sufficient, you must read the book for better understanding. Lecture notes are just implementing the concepts of the book on a dataset, but not explaining the concepts elaborately.*

```
import pandas as pd
import numpy as np
import statsmodels.formula.api as smf
import statsmodels.api as sm
import seaborn as sns
import matplotlib.pyplot as plt
from patsy import dmatrix
from sklearn.metrics import mean_squared_error
from pyearth import Earth
from sklearn.linear_model import LinearRegression
```

```
#Using the same datasets as used for linear regression in STAT303-2,
#so that we can compare the non-linear models with linear regression
trainf = pd.read_csv('./Datasets/Car_features_train.csv')
trainp = pd.read_csv('./Datasets/Car_prices_train.csv')
testf = pd.read_csv('./Datasets/Car_features_test.csv')
testp = pd.read_csv('./Datasets/Car_prices_test.csv')
train = pd.merge(trainf, trainp)
test = pd.merge(testf, testp)
train.head()
```

	carID	brand	model	year	transmission	mileage	fuelType	tax	mpg	engineSize	price

## 2.1 Polynomial regression vs Regression splines

### 2.1.1 Model of degree 1

	mileage
0	11
1	10813
2	6
3	18895
4	62953
...	...
4955	34416
4956	21227
4957	121349
4958	21491
4959	45000

```
X = pd.DataFrame(trainf['mileage'])
y = trainp['price']
lr_model = LinearRegression()
lr_model.fit(X, y)

ols_object = smf.ols(formula = 'price~mileage', data = train)
lr_model = ols_object.fit()
```

```
lr_model.params
```

```
Intercept    31488.731916
mileage      -0.321313
dtype: float64
```

```
lr_model.coef_
```

```
array([-0.00208937])
```

```

#Regression spline of degree 1

#Creating basis functions for splines of degree 1
transformed_x = dmatrix("bs(mileage , knots=(33000,66000,100000), degree = 1, include_intercept=True)",
                        data = trainf,return_type = 'dataframe')

#Developing a linear regression model on the spline basis functions - this is the regression model
reg_spline_model = LinearRegression()
reg_spline_model.fit(transformed_x, trainp['price']);

#Visualizing polynomial model and the regression spline model of degree 1

knots = [33000,66000,100000] #Knots for the spline
d=1 #Degree of predictor in the model
#Writing a function to visualize polynomial model and the regression spline model of degree d
def viz_models():
    fig, axes = plt.subplots(1,2,figsize = (15,5))
    plt.subplots_adjust(wspace=0.2)

    #Visualizing the linear regression model
    pred_price = lr_model.predict(X)
    sns.scatterplot(ax = axes[0],x = 'mileage', y = 'price', data = train, color = 'orange')
    sns.lineplot(ax = axes[0],x = train.mileage, y = pred_price, color = 'blue')
    axes[0].set_title('Polynomial regression model of degree '+str(d))

    #Visualizing the regression splines model of degree 'd'
    axes[1].set_title('Regression splines model of degree '+ str(d))
    sns.scatterplot(ax=axes[1],x = 'mileage', y = 'price', data = train, color = 'orange')
    sns.lineplot(ax=axes[1],x = train.mileage, y = reg_spline_model.predict(transformed_x))
    for i in range(3):
        plt.axvline(knots[i], 0,100,color='red')
viz_models()

```

We observe the regression splines model better fits the data as compared to the polynomial regression model. This is because regression splines of degree 1 fit piecewise polynomials, or linear models on sub-sections of the predictor, which helps better capture the trend. However, this added flexibility may also lead to overfitting. Hence, one must be careful to check for overfitting when using splines. Overfitting may be checked by k-fold cross validation or comparing test and train errors.

The red lines in the plot on the right denote the position of knots. Knots separate distinct splines.

```
#Creating basis functions for test data for prediction
test_x = dmatrix("bs(mileage , knots=(33000,66000,100000), degree = 1, include_intercept =

#Function to compute RMSE (root mean squared error on train and test datasets)
def rmse():
    #Error on train data for the linear regression model
    print("RMSE on train data:")
    print("Linear regression:", np.sqrt(mean_squared_error(lr_model.predict(),train.price))

    #Error on train data for the regression spline model
    print("Regression splines:", np.sqrt(mean_squared_error(reg_spline_model.predict(),tra

    #Error on test data for the linear regression model
    print("\nRMSE on test data:")
    print("Linear regression:",np.sqrt(mean_squared_error(lr_model.predict(test),test.pric

    #Error on test data for the regression spline model
```

```
print("Regression splines:", np.sqrt(mean_squared_error(reg_spline_model.predict(test_x),
rmse())
```

RMSE on train data:

Linear regression: 14403.250083261853

Regression splines: 13859.640716531134

RMSE on test data:

Linear regression: 14370.94086395544

Regression splines: 13770.133025694666

### 2.1.2 Model of degree 2

A higher degree model will lead to additional flexibility for both polynomial and regression splines models.

```
#Including mileage squared as a predictor and developing the model
ols_object = smf.ols(formula = 'price~mileage+I(mileage**2)', data = train)
lr_model = ols_object.fit()

#Regression spline of degree 2

#Creating basis functions for splines of degree 2
transformed_x = dmatrix("bs(mileage , knots=(33000,66000,100000), degree = 2, include_intercept=True",
                        data = {'mileage':train['mileage']},return_type = 'dataframe')

#Developing a linear regression model on the spline basis functions - this is the regression spline model
reg_spline_model = sm.OLS(train['price'], transformed_x).fit()

d=2
viz_models()
```

Unlike polynomial regression, splines functions avoid imposing a global structure on the non-linear function of  $X$ . This provides a better local fit to the data.

```
#Creating basis functions for test data for prediction
test_x = dmatrix("bs(mileage , knots=(33000,66000,100000), degree = 2, include_intercept = 1)", data = test)

rmse()
```

RMSE on train data:

Linear regression: 14403.250083261853

Regression splines: 13859.640716531134

RMSE on test data:

Linear regression: 14370.94086395544

Regression splines: 13770.133025694666

### 2.1.3 Model of degree 3

```
ols_object = smf.ols(formula = 'price~mileage+I(mileage**2)+I(mileage**3)', data = train)
lr_model = ols_object.fit()

#Regression spline of degree 3

#Creating basis functions for splines of degree 3
transformed_x = dmatrix("bs(mileage , knots=(20000,40000,80000), degree = 3, include_intercept = 1)", data = train)
```

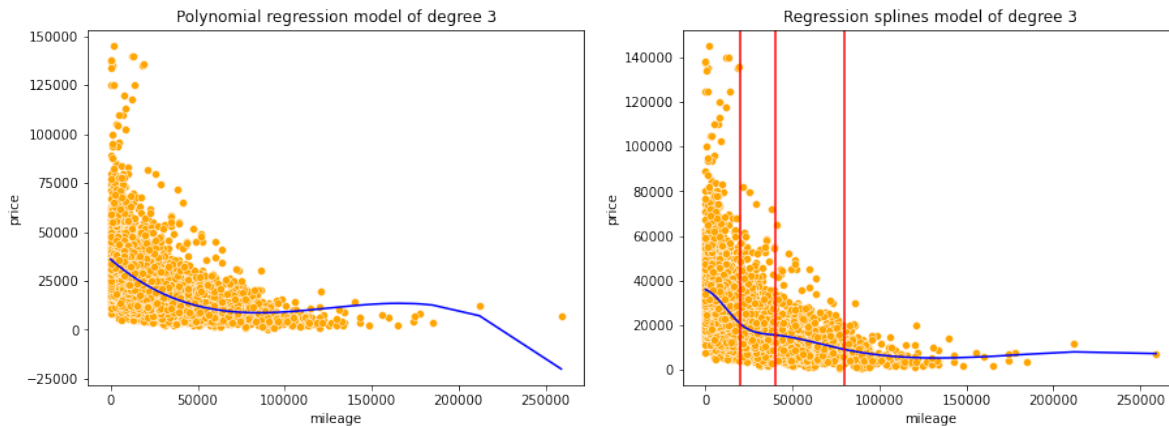

```
data = {'mileage':train['mileage']},return_type = 'dataframe')

#Developing a linear regression model on the spline basis functions - this is the regression
reg_spline_model = sm.OLS(train['price'], transformed_x).fit()
```

```
transformed_x
```

	Intercept	bs(mileage, knots=(20000, 40000, 80000), degree=3, include__intercept=False)[0]	bs(mileage
0	1.0	0.001499	3.749187
1	1.0	0.583162	3.001491

...	...	...	...
4955	1.0	0.005441	4.824519
4956	1.0	0.206763	6.438755
4957	1.0	0.000000	0.000000
4958	1.0	0.198162	6.468919
4959	1.0	0.000000	2.233101

```
d=3
knots=[20000,40000,80000]
viz_models()
```

Unlike polynomial regression, splines functions avoid imposing a global structure on the non-linear function of X. This provides a better local fit to the data.

```
#Creating basis functions for test data for prediction
test_x = dmatrix("bs(mileage , knots=(20000,40000,80000), degree = 3, include_intercept =
```

```
rmse()
```

RMSE on train data:

Linear regression: 13891.962447594644

Regression splines: 13792.371446327243

RMSE on test data:

Linear regression: 13789.708418357186

Regression splines: 13651.288965905529

## 2.2 Regression splines with knots at uniform quantiles of data

If degrees of freedom are provided instead of knots, the knots are by default chosen at uniform quantiles of data. For example if there are 7 degrees of freedom (including the intercept), then there will be  $7-4 = 3$  knots. These knots will be chosen at the 25th, 50th and 75th quantiles of the data.

```
#Regression spline of degree 3
```

```
#Creating basis functions for splines of degree 3
```

```
transformed_x = dmatrix("bs(mileage , df=6, degree = 3, include_intercept = False)",
                        data = {'mileage':train['mileage']},return_type = 'dataframe')
```

```
#Developing a linear regression model on the spline basis functions - this is the regression
```

```
reg_spline_model = sm.OLS(train['price'], transformed_x).fit()
```

```
d=3
```

```
unif_knots = pd.qcut(train.mileage,4,retbins=True)[1][1:4]
```

```
knots=unif_knots
```

```
viz_models()
```

Splines can be unstable at the outer range of predictors. In the figure (on the right), the left-most spline may be overfitting.

```
#Creating basis functions for test data for prediction
test_x = dmatrix("bs(mileage , knots=" +str(tuple(unif_knots))) + ", degree = 3, include_in

rmse()
```

RMSE on train data:

Linear regression: 13891.962447594644

Regression splines: 13781.79102252679

RMSE on test data:

Linear regression: 13789.708418357186

Regression splines: 13676.271829882426

## 2.3 Natural cubic splines

Page 298: “A natural spline is a regression spline with additional boundary constraints: the function is required to be linear at the boundary (in the region where  $X$  is smaller than the smallest knot, or larger than the largest knot). This additional constraint means that natural splines generally produce more stable estimates at the boundaries.”

```
#Natural cubic spline
```

```
#Creating basis functions for the natural cubic spline
transformed_x = dmatrix("cr(mileage , df=4,constraints='center')",
                        data = {'mileage':train['mileage']},return_type = 'dataframe')
reg_spline_model = sm.GLM(train['price'], transformed_x).fit()
```

```
d=3;
unif_knots = pd.qcut(train.mileage,4,retbins=True)[1][1:4]
knots=unif_knots
viz_models()
```

Note that the natural cubic spline is more stable than a cubic splines with knots at uniformly distributed quantiles.

```
#Creating basis functions for test data for prediction
test_x = dmatrix("cr(mileage , knots="+str(tuple(unif_knots))+",constraints='center')",data=test_data)

rmse()
```

RMSE on train data:

Linear regression: 13891.962447594644

Regression splines: 13805.022189679756

RMSE on test data:

Linear regression: 13789.708418357186

Regression splines: 13666.943224268975

## 2.4 Generalized additive model (GAM)

GAM allow for flexible nonlinearities in several variables, but retain the additive structure of linear models. In a GAM, non-linear basis functions of predictors can be used as predictors of a linear regression model. For example,

$$y = f_1(X_1) + f_2(X_2) + \epsilon$$

is a GAM, where  $f_1(\cdot)$  may be a cubic spline based on the predictor  $X_1$ , and  $f_2(\cdot)$  may be a step function based on the predictor  $X_2$ .

```
sns.distplot(train.year)
```

```

MARS provides a better fit than the splines that we used above. This is because MARS tunes the positions of the knots and considers interactions (also with tuned knots) to improve the model fit. Tuning of knots may improve the fit of splines as well.

### 2.5.3 MARS including categorical variables

```
#A categorical variable can be turned to dummy variables to use the Earth package for fitting
train_cat = pd.concat([train,pd.get_dummies(train.fuelType)],axis=1)
test_cat = pd.concat([test,pd.get_dummies(test.fuelType)],axis=1)
```

```
train_cat.head()
```

8729.912066822455

The RMSE for the MARS model is lesser than that of the linear regression model, as expected.

# A Assignment A

1. You may talk to a friend, discuss the questions and potential directions for solving them. However, you need to write your own solutions and code separately, and not as a group activity.
2. Do not write your name on the assignment.
3. Write your code in the *Code* cells and your answer in the *Markdown* cells of the Jupyter notebook. Ensure that the solution is written neatly enough to understand and grade.
4. Use [Quarto](#) to print the *.ipynb* file as HTML. You will need to open the command prompt, navigate to the directory containing the file, and use the command: `quarto render filename.ipynb --to html`. Submit the HTML file.
5. The assignment is worth 100 points, and is due on **Thursday, 13th April 2023 at 11:59 pm**.
6. **Four points are properly formatting the assignment.** The breakdown is as follows:
  - Must be an HTML file rendered using Quarto (1 pt). *If you have a Quarto issue, you must mention the issue & quote the error you get when rendering using Quarto in the comments section of Canvas, and submit the ipynb file. If your issue doesn't seem genuine, you will lose points.*
  - There aren't excessively long outputs of extraneous information (e.g. no printouts of entire data frames without good reason, there aren't long printouts of which iteration a loop is on, there aren't long sections of commented-out code, etc.) (1 pt)
  - Final answers of each question are written in Markdown cells (1 pt).
  - There is no piece of unnecessary / redundant code, and no unnecessary / redundant text (1 pt)

## A.1 Bias-variance trade-off

Throughout the course, the conceptual clarity about bias and variance will help you tune the models for optimal performance and enable you to compare different models in terms of bias and variance. In this question, you will perform simulations to understand and visualize bias-variance trade-off as in Fig. 2.12 of the [book](#) (page 36).

Assume that the response  $y$  is a function of the predictors  $x_1$  and  $x_2$  and includes a random error  $\epsilon$ , as follows:

$$y = f(x_1, x_2) + \epsilon, \quad (\text{A.1})$$

where the function  $f(\cdot)$  is the [Bukin function](#),  $x_1 \sim U[-15, -5]$ ,  $x_2 \sim U[-3, 3]$ , and  $\epsilon \sim N(0, \sigma^2)$ ;  $\sigma = 10$ . Here  $U$  refers to Uniform distribution, and  $N$  refers to normal distribution.

You will code an algorithm (described below) to compute the expected squared bias, expected variance,  $\text{var}(\epsilon)$  and expected test MSE of the following 7 linear regression models having the predictors as:

1.  $x_1$  and  $x_2$
2. All the predictors in the above model, and all polynomial combinations of  $x_1$ , and  $x_2$  of degree 2, which will be  $x_1^2, x_2^2$ , and  $x_1x_2$
3. All the predictors in the above model, and all polynomial combinations of  $x_1$ , and  $x_2$  of degree 3, which will be  $x_1^3, x_2^3, x_1^2x_2$ , and  $x_1x_2^2$
4. All the predictors in the above model, and all polynomial combinations of  $x_1$ , and  $x_2$  of degree 4
5. All the predictors in the above model, and all polynomial combinations of  $x_1$ , and  $x_2$  of degree 5
6. All the predictors in the above model, and all polynomial combinations of  $x_1$ , and  $x_2$  of degree 6
7. All the predictors in the above model, and all polynomial combinations of  $x_1$ , and  $x_2$  of degree 7

As you can see the models are arranged in increasing order of flexibility / complexity. This corresponds to the horizontal axis of Fig. 2.12 in the book.

Use the following **algorithm** to compute the expected squared bias, expected variance,  $\text{var}(\epsilon)$  and expected test MSE of the 7 linear regression models above:

**I. Define the Bukin function** that accepts  $x_1$  and  $x_2$  as parameters and returns the Bukin function value ( $f(x_1, x_2)$ ).

(2 points)

**II.** Considering a model of **degree**  $d$ , simulate the following test and train datasets.

**A. Simulate test data**

1. Simulate 100 values of  $x_1$  from  $U[-15, -5]$

2. Simulate 100 values of  $x_2$  from  $U[-3, 3]$
3. Compute the Bukin function value  $f(x_1, x_2)$  for the simulated values of  $x_1$  and  $x_2$ .
4. Use the function `PolynomialFeatures` from the `preprocessing` module of the `sklearn` library to create all polynomial combinations of  $x_1$ , and  $x_2$  up to degree  $d$ .

(4 points)

**B. Simulate 100 train data sets**, where each train data is simulated as follows:

1. Simulate 100 values of  $x_1$  from  $U[-15, -5]$
2. Simulate 100 values of  $x_2$  from  $U[-3, 3]$
3. Compute the Bukin function value  $f(x_1, x_2)$  for the simulated values of  $x_1$  and  $x_2$
4. Simulate the response  $y$  using the above set of simulated values with Equation [A.1](#)
5. Use the function `PolynomialFeatures` from the `preprocessing` module of the `sklearn` library to create all polynomial combinations of  $x_1$ , and  $x_2$  up to degree  $d$ .

(6 points)

**III.** For each train data in II(B), develop a linear regression model using the `LinearRegression()` function from the `linear_model` module of the `sklearn` library.

(2 points)

**IV.** Note that the squared bias at a test point  $x_{1\_test}, x_{2\_test}$  is:

$$[Bias(\hat{f}(x_{1\_test}, x_{2\_test}))]^2 = [E(\hat{f}(x_{1\_test}, x_{2\_test})) - f(x_{1\_test}, x_{2\_test})]^2, \quad (\text{A.2})$$

where  $E(\hat{f}(x_{1\_test}, x_{2\_test}))$  is the mean prediction of the 100 trained models at  $x_{1\_test}, x_{2\_test}$ .

Compute the overall expected squared bias as the average squared bias at all the test data points, as in the equation below:

$$[Bias(\hat{f}(.))]^2 = \frac{1}{100} \sum_{i=1}^{100} [Bias(\hat{f}(x_{i\_test}, x_{i\_test}))]^2, \quad (\text{A.3})$$

(8 points)

**V.** Note that the variance at a test point  $x_{1\_test}, x_{2\_test}$  is  $Var(\hat{f}(x_{1\_test}, x_{2\_test}))$ . Compute the overall expected variance as the average variance at all the test data points, as in the equation below:

$$Var(\hat{f}(.)) = \frac{1}{100} \sum_{i=1}^{100} Var(\hat{f}(x_{i\_test}, x_{i\_test})) \quad (\text{A.4})$$

(6 points)

**VI.** Compute the overall expected test mean squared error as the sum of the expected squared bias (equation 3), expected variance (equation 4), and error variance ( $\sigma^2$ ):

$$MSE = [Bias(\hat{f}(.))]^2 + Var(\hat{f}(.)) + \sigma^2, \quad (\text{A.5})$$

(4 points)

**VII.** Repeat steps II - VI for all degrees  $d$  in  $\{1, 2, \dots, 7\}$

(3 points)

**VIII.** Plot the overall expected squared bias, overall expected variance, and overall expected test MSE (as obtained from Equation A.3, Equation A.4, and Equation A.5 respectively) against the degree  $d$  (or flexibility / complexity) of the model . Your plot should look like one of the plots in Fig. 2.12 of the book.

(3 points)

**IX.** What is the degree of the optimal model?

(2 points)

*Note: While coding the algorithm, comment it well so that it is easy to give partial credit in case of mistakes. Include the numerals of the algorithm (such as II(B), V, VI, etc.) in your comments so that it is easier to navigate your algorithm.*

## A.2 Tuning a classification model with sklearn

### Data

Read the data `classification_data.csv`. The description of the columns is as follows:

1. `hi_int_prncp_pd`: Indicates if a high percentage of the repayments made went to interest rather than principal. **Target variable.**
2. `out_prncp_inv`: Remaining outstanding principal for portion of total amount funded by investors
3. `loan_amnt`: The listed amount of the loan applied for by the borrower. If at some point in time, the credit department reduces the loan amount, then it will be reflected in this value.

4. `int_rate`: Interest rate on the loan
5. `term`: The number of payments on the loan. Values are in months and can be either 36 or 60.

You will develop and tune a logistic regression model to predict `hi_int_prncp_pd` based on the rest of the columns (predictors) as per the instructions below.

### A.2.1 Train-test split

Use the function `train_test_split` from the `model_selection` module of the `sklearn` library to split the data into 75% train and 25% test. Stratify the split based on the response. Use `random_state` as 45. Print the proportion of 0s and 1s in both the train and test datasets.

*(4 points)*

### A.2.2 Scaling predictors

Scale the predictors to avoid convergence errors when fitting the logistic regression model.

*Note that last quarter, we were also focusing on inference, so we avoided scaling. It is a bit inconvenient to interpret odds with scaled predictors. However, avoiding scaling may lead to convergence errors as some of you saw in your course projects. So, it is a good practice to scale, especially when your focus is prediction.*

### A.2.3 Tuning the degree

Use the functions:

1. `cross_val_score` from the `model_selection` module of the `sklearn` library to tune the degree of the logistic regression model for maximizing the stratified 5-fold prediction accuracy. Consider degrees from 1 to 6.
2. `PolynomialFeatures` from the `preprocessing` module of the `sklearn` library to create all polynomial combinations of the predictors up to degree  $d$ .

What is the optimal degree?

*(4 points)*

**Notes:**

- A model of degree  $d$  will consist of polynomial transformations and interactions of predictors up to degree  $d$ . For example, a model of degree 2 will consist of the square of each predictor and all 2-factor interactions of the predictors.

- You may use the `newton-cg` solver to avoid convergence issues.
- Use the default `C` value at this point, you will tune it later.

#### **A.2.4 Test accuracy with tuned degree**

For the optimal degree identified in the previous question, compute the test accuracy.

*(4 points)*

#### **A.2.5 Tuning C**

With the optimal degree identified in the previous question, find the optimal regularization parameter `C`. Again use the `cross_val_score` function.

*(4 points)*

#### **A.2.6 Test accuracy with optimal degree and C**

For the optimal degree and optimal `C` identified in the previous questions, compute the test accuracy.

*(4 points)*

#### **A.2.7 Optimal decision threshold probability**

With the optimal degree and optimal `C` identified in the previous questions, find the optimal decision threshold probability to maximize accuracy. Use the `cross_val_predict` function.

*(4 points)*

#### **A.2.8 Test accuracy for optimal degree, C, and threshold probability**

For the optimal degree, optimal `C`, and optimal decision threshold probabilities identified in the previous questions, compute the test accuracy.

*(4 points)*

### A.2.9 Simultaneous optimization of multiple parameters

In the above tuning approach we optimized the hyperparameters and the decision threshold probability sequentially. This is a greedy approach, which doesn't consider all combinations of hyperparameters and decision threshold probabilities, and thus may fail to find the optimal combination of values that maximize accuracy. Thus, tune both the model hyperparameters - degree and C, and the decision threshold probability simultaneously considering all value combinations. This will take more time, but is likely to provide more accurate optimal parameter values.

*(6 points)*

### A.2.10 Test accuracy with optimal parameters obtained simultaneously

For the optimal degree, optimal C, and optimal decision threshold probabilities identified in the previous question, compute the test accuracy.

*(4 points)*

### A.2.11 Optimizing parameters for multiple performance metrics

Find the optimal C and degree to maximize recall while having a precision of more than 75%. Use the function `cross_validate` from the `model_selection` module of the `sklearn` library.

*Note: `cross_validate` function is very similar to `cross_val_score`, the only difference is you can use multiple metrics with the scoring input, as you need in this question.*

*(8 points)*

### A.2.12 Performance metrics computation

For the optimal degree and C identified in the previous question, compute the following performance metrics on test data. Use `sklearn` functions, manual computation is not allowed.

1. Precision
2. Recall
3. Accuracy
4. ROC-AUC
5. Show the confusion matrix

*(10 points)*

## B Stratified splitting (classification problem)

### B.1 Stratified splitting with respect to response

**Q:** When splitting data into train and test for developing and assessing a classification model, it is recommended to stratify the split with respect to the response. Why?

**A:** The main advantage of stratified splitting is that it can help ensure that the training and testing sets have similar distributions of the target variable, which can lead to more accurate and reliable model performance estimates.

In many real-world datasets, the target variable may be imbalanced, meaning that one class is more prevalent than the other(s). For example, in a medical dataset, the majority of patients may not have a particular disease, while only a small fraction may have the disease. If a random split is used to divide the dataset into training and testing sets, there is a risk that the testing set may not have enough samples from the minority class, which can lead to biased model performance estimates.

Stratified splitting addresses this issue by ensuring that both the training and testing sets have similar proportions of the target variable. This can lead to more accurate model performance estimates, especially for imbalanced datasets, by ensuring that the testing set contains enough samples from each class to make reliable predictions.

Another advantage of stratified splitting is that it can help ensure that the model is not overfitting to a particular class. If a random split is used and one class is overrepresented in the training set, the model may learn to predict that class well but perform poorly on the other class(es). Stratified splitting can help ensure that the model is exposed to a representative sample of all classes during training, which can improve its generalization performance on new, unseen data.

In summary, the advantages of stratified splitting are that it can lead to more accurate and reliable model performance estimates, especially for imbalanced datasets, and can help prevent overfitting to a particular class.

## B.2 Stratified splitting with respect to response and categorical predictors

**Q:** Will it be better to stratify the split with respect to the response as well as categorical predictors, instead of only the response? In that case, the train and test datasets will be even more representative of the complete data.

**A:** It is not recommended to stratify with respect to both the response and categorical predictors simultaneously, while splitting a dataset into train and test, because doing so may result in the test data being very similar to train data, thereby defeating the purpose of assessing the model on unseen data. This kind of a stratified splitting will tend to make the relationships between the response and predictors in train data also appear in test data, which will result in the performance on test data being very similar to that in train data. Thus, in this case, the ability of the model to generalize to new, unseen data won't be assessed by test data.

Therefore, it is generally recommended to only stratify the response variable when splitting the data for model training, and to use random sampling for the predictor variables. This helps to ensure that the model is able to capture the underlying relationships between the predictor variables and the response variable, while still being able to generalize well to new, unseen data.

In the extreme scenario, when there are no continuous predictors, and there are enough observations for stratification with respect to the response and the categorical predictors, the train and test datasets may turn out to be exactly the same. Example 1 below illustrates this scenario.

## B.3 Example 1

The example below shows that the train and test data can be exactly the same if we stratify the split with respect to response and the categorical predictors.

```
# Importing necessary libraries
import pandas as pd
import numpy as np
import matplotlib.pyplot as plt
import seaborn as sns
from sklearn.linear_model import LogisticRegression
from sklearn.model_selection import train_test_split, cross_val_predict, cross_val_score
from sklearn.metrics import accuracy_score
from itertools import product
sns.set(font_scale=1.35)
```

Let us simulate a dataset with 8 observations, two categorical predictors `x1` and `x2` and the binary response `y`.

```
#Setting a seed for reproducible results
np.random.seed(9)

# 8 observations
n = 8

#Simulating the categorical predictors
x1 = pd.Series(np.random.randint(0,2,n), name = 'x1')
x2 = pd.Series(np.random.randint(0,2,n), name = 'x2')

#Simulating the response
pr = (x1==1)*0.7+(x2==0)*0.3# + (x3*0.1>0.1)*0.1
y = pd.Series(1*(np.random.uniform(size = n) < pr), name = 'y')

#Defining the predictor object 'X'
X = pd.concat([x1, x2], axis = 1)

#Stratified splitting with respect to the response and predictors to create 50% train and
X_train_stratified, X_test_stratified, y_train_stratified,\
y_test_stratified = train_test_split(X, y, test_size = 0.5, random_state = 45, stratify=da

#Train and test data resulting from the above stratified splitting
data_train = pd.concat([X_train_stratified, y_train_stratified], axis = 1)
data_test = pd.concat([X_test_stratified, y_test_stratified], axis = 1)
```

Let us check the train and test datasets created with stratified splitting with respect to both the predictors and the response.

`data_train`

	x1	x2	y
2	0	0	1
7	0	1	0
3	1	0	1
1	0	1	0

`data_test`

	x1	x2	y
4	0	1	0
6	1	0	1
0	0	1	0
5	0	0	1

Note that the train and test datasets are exactly the same! Stratified splitting tends to have the same proportion of observations corresponding to each strata in both the train and test datasets, where each strata is a unique combination of values of **x1**, **x2**, and **y**. This will tend to make the train and test datasets quite similar!

## B.4 Example 2: Simulation results

The example below shows that train and test set performance will tend to be quite similar if we stratify the datasets with respect to the predictors and the response.

We'll simulate a dataset consisting of 1000 observations, 2 categorical predictors **x1** and **x2**, a continuous predictor **x3**, and a binary response **y**.

```
#Setting a seed for reproducible results
np.random.seed(99)

# 1000 Observations
n = 1000

#Simulating categorical predictors x1 and x2
x1 = pd.Series(np.random.randint(0,2,n), name = 'x1')
x2 = pd.Series(np.random.randint(0,2,n), name = 'x2')

#Simulating continuous predictor x3
x3 = pd.Series(np.random.normal(0,1,n), name = 'x3')

#Simulating the response
pr = (x1==1)*0.7+(x2==0)*0.3 + (x3*0.1>0.1)*0.1
y = pd.Series(1*(np.random.uniform(size = n) < pr), name = 'y')

#Defining the predictor object 'X'
X = pd.concat([x1, x2, x3], axis = 1)
```

We'll comparing model performance metrics when the data is split into train and test by performing stratified splitting

1. Only with respect to the response
2. With respect to the response and categorical predictors

We'll perform 1000 simulations, where the data is split using a different seed in each simulation.

```
#Creating an empty dataframe to store simulation results of 1000 simulations
accuracy_iter = pd.DataFrame(columns = {'train_y_stratified','test_y_stratified',
                                         'train_y_CatPredictors_stratified','test_y_CatPred

# Comparing model performance metrics when the data is split into train and test by perform
# (1) only with respect to the response
# (2) with respect to the response and categorical predictors

# Stratified splitting is performed 1000 times and the results are compared
for i in np.arange(1,1000):

    #-----Case 1-----#
    # Stratified splitting with respect to response only to create train and test data
    X_train, X_test, y_train, y_test = train_test_split(X, y, test_size = 0.2, random_stat
    model = LogisticRegression()
    model.fit(X_train, y_train)

    # Model accuracy on train and test data, with stratification only on response while sp
    # the complete data into train and test
    accuracy_iter.loc[(i-1), 'train_y_stratified'] = model.score(X_train, y_train)
    accuracy_iter.loc[(i-1), 'test_y_stratified'] = model.score(X_test, y_test)

    #-----Case 2-----#
    # Stratified splitting with respect to response and categorical predictors to create t
    # and test data
    X_train, X_test, y_train, y_test = train_test_split(X, y, test_size = 0.2, random_stat
                                                stratify=pd.concat([x1, x2, y], ax
    model.fit(X_train, y_train)

    # Model accuracy on train and test data, with stratification on response and predictor
    # splitting the complete data into train and test
    accuracy_iter.loc[(i-1), 'train_y_CatPredictors_stratified'] = model.score(X_train, y_
    accuracy_iter.loc[(i-1), 'test_y_CatPredictors_stratified'] = model.score(X_test, y_te

# Converting accuracy to numeric
```

```
accuracy_iter = accuracy_iter.apply(lambda x:x.astype(float), axis = 1)
```

## Distribution of train and test accuracies

The table below shows the distribution of train and test accuracies when the data is split into train and test by performing stratified splitting:

1. Only with respect to the response (see `train_y_stratified` and `test_y_stratified`)
2. With respect to the response and categorical predictors (see `train_y_CatPredictors_stratified` and `test_y_CatPredictors_stratified`)

```
accuracy_iter.describe()
```

	train_y_stratified	test_y_stratified	train_y_CatPredictors_stratified	test_y_CatPredictors_stratified
count	999.000000	999.000000	9.990000e+02	9.990000e+02
mean	0.834962	0.835150	8.350000e-01	8.350000e-01
std	0.005833	0.023333	8.552999e-15	8.552999e-15
min	0.812500	0.755000	8.350000e-01	8.350000e-01
25%	0.831250	0.820000	8.350000e-01	8.350000e-01
50%	0.835000	0.835000	8.350000e-01	8.350000e-01
75%	0.838750	0.850000	8.350000e-01	8.350000e-01
max	0.855000	0.925000	8.350000e-01	8.350000e-01

Let us visualize the distribution of these accuracies.

### B.4.1 Stratified splitting only with respect to the response

```
sns.histplot(data=accuracy_iter, x="train_y_stratified", color="red", label="Train accuracies")
sns.histplot(data=accuracy_iter, x="test_y_stratified", color="skyblue", label="Test accuracies")
plt.legend()
plt.xlabel('Accuracy')
```

```
Text(0.5, 0, 'Accuracy')
```

Note the variability in train and test accuracies when the data is stratified only with respect to the response. The train accuracy varies between 81.2% and 85.5%, while the test accuracy varies between 75.5% and 92.5%.

#### B.4.2 Stratified splitting with respect to the response and categorical predictors

```
sns.histplot(data=accuracy_iter, x="train_y_CatPredictors_stratified", color="red", label=
sns.histplot(data=accuracy_iter, x="test_y_CatPredictors_stratified", color="skyblue", lab
plt.legend()
plt.xlabel('Accuracy')
```

```
Text(0.5, 0, 'Accuracy')
```

The train and test accuracies are between 85% and 85.5% for all the simulations. As a results of stratifying the splitting with respect to both the response and the categorical predictors, the train and test datasets are almost the same because the datasets are engineered to be quite similar, thereby making the test dataset inappropriate for assessing accuracy on unseen data. Thus, it is recommended to stratify the splitting only with respect to the response.

## C Datasets, assignment and project files
